ETR-concept an ecological concept based on the energetics of water

- Dissipative structures are the optimized energetic answers to material interaction problems, far from thermodynamic equilibrium. Patterns are created.

- The efficiency criteria (closed localized material cycles related to irreversible linear material flow) determines sustainability of dissipative structures

- Periodically moving water in nature, metabolizing cells, reproducing organisms, coenotic structures competing for sustainability are selfoptimizing systems and dissipative structures in different fractal organization levels

Nature as a dynamic energy-dissipative process

- Structures and distributes processes by means of the dynamic medium water in landscape
- It controlles the atmosphere with respect to its process dynamics,
composition und distribution
- It controlles mechanical and chemical processes close to the soil surface and distributes thereby organisms, it eliminates randomness, minimises material flows, and increases sustainable development
- It controlles temperature- and moisture patterns in space and time as a niche for all organisms

Processor properties of water

Alternating current
periods
day/year

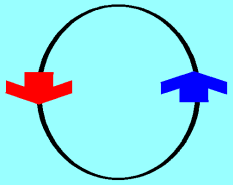
Energy

Mean
energy
350 Watt/m^2

energy-dissipative processor water and biological cells

physical property

condensation



Evaporation

Carnot cycle

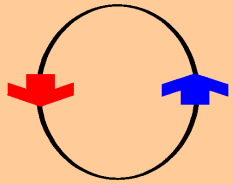
atmosphere

continents → sea

cooling function
almost no losses
space related

chemical property

precipitation



dissolution

Efficiency and selfoptimization in nature (ETR-concept)

- Dissipative structures are the optimized material answers to energetic interaction problems far from thermodynamic equilibrium
- The efficiency criteria (closed localized material cycles related to irreversible linear material flow) determines sustainability of dissipative structures
- Periodically moving water in nature, metabolizing cells, reproducing organisms, coenotic structures competing for sustainability and selfoptimizing ecosystems are dissipative structures in different fractal organization levels

Theoretical basis for thermal efficiency

$$\frac{\text{mean temperature} - \text{temperature deviation}}{\text{mean temperature}}$$

increasing efficiency = minimal temperature deviation

decreasing efficiency = maximal temperature deviation

mean temperature = because of vertical gradients and different heat capacity of air, soil and water mean temperature is difficult to estimate in practice

temperature deviation = deviation of real, actual temperature from the mean temperature

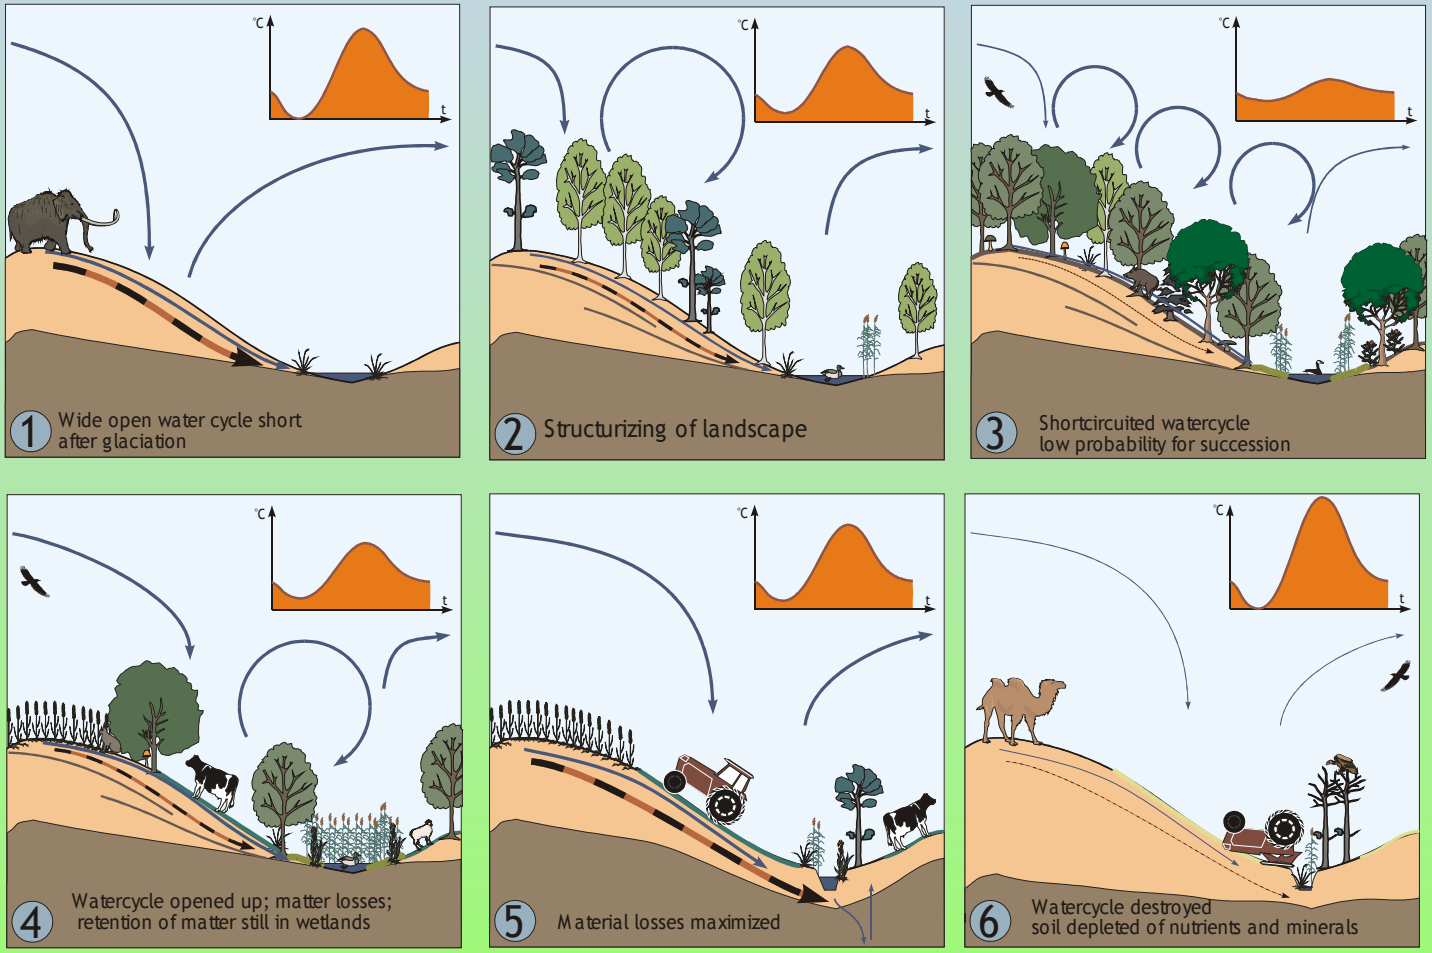
Development and Desertification of Landscape after glaciation had ceased

Water cycle, matter budget and temperature balance

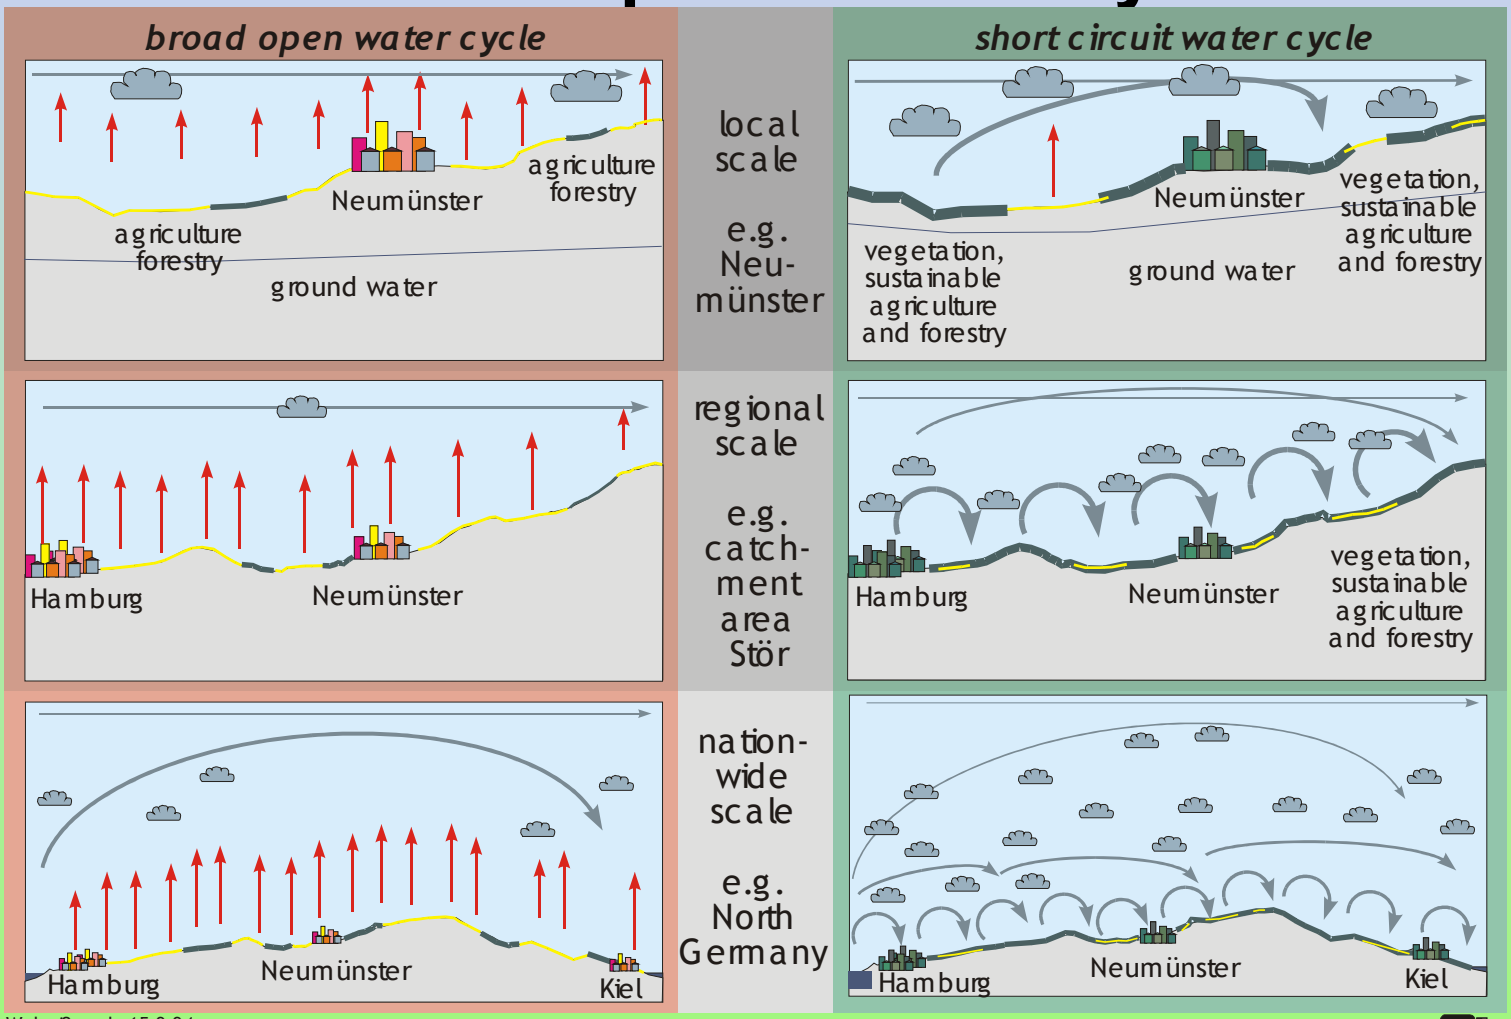


histor3a.cdr 20010810, Christian Hildmann

ETR an ecological concept based on the energetics of water

- Water in interaction with solid surface leads to sorting processes according to energetic dissipative properties (particle size, dissolution equilibria)
- stagnant water leads to conservation of structures (achievement of equilibrium)
- high and random water dynamics at liquid-solid interfaces lead to erosion of structures (increased mechanical and chemical interactions)
- optimized dissipative structures are dynamic metabolizing structures at lowest energy flow density

The dissipative water cycle



Indicators for sustainable and non-sustainable water cycles and landscapes

What are Natures ecological services for a sustainable society?

- The dissipative water cycle, evaporation and precipitation and its thermostatic function in the catchments
- The atmosphere in its composition, its distribution and its dynamics
- Soil fertility at dynamic conditions. Soil as the dynamic interface between vegetation and the minerogenic substrate under the local water-cycle conditions
- The selforganizing plant cover as the efficient protector of habitat stability
