Summary

This study was undertaken to determine pattern sensitivity of phrenic nerve plasticity in respect to different respiratory challenges. We compared long-term effects of intermittent and continuous hypercapnic and hypoxic stimuli, and combined intermittent hypercapnia and hypoxia on phrenic nerve plasticity. Adult, male, urethane-anesthetized, vagotomized, paralyzed, mechanically ventilated Sprague-Dawley rats were exposed to: acute intermittent hypercapnia (AIHc or AIH_{CO₂}), acute intermittent hypoxia (AIH), combined intermittent hypercapnia and hypoxia (AIHCh), continuous hypercapnia (CHc), or continuous hypoxia (CH). Peak phrenic nerve activity (pPNA) and burst frequency were analyzed during baseline (T0), hypercapnia or hypoxia exposures, at 15, 30, and 60 min (T60) after the end of the stimulus. Exposure to acute intermittent hypercapnia elicited decrease of phrenic nerve frequency from 44.25±4.06 at T0 to 35.29±5.21 at T60, ($P=0.038$, AIHc) and from 45.5±2.62 to 37.17±3.68 breaths/min ($P=0.049$, AIH_{CO₂}), i.e. frequency phrenic long term depression was induced. Exposure to AIH elicited increase of pPNA at T60 by 141.0±28.2 % compared to baseline ($P=0.015$), i.e. phrenic long-term facilitation was induced. Exposure to AIHCh, CHc, or CH protocols failed to induce long-term plasticity of the phrenic nerve. Thus, we conclude that intermittency of the hypercapnic or hypoxic stimuli is needed to evoke phrenic nerve plasticity.

Key words

Hypercapnia • Hypoxia • Phrenic nerve • Respiratory plasticity • Rat

Introduction

Neuroplasticity is an important property of the respiratory system whose functionality and biological significance has been recognized in recent years. Its clinical significance is related to the pathology of several medical conditions (Dale *et al.* 2014), including sleep-related breathing disorders characterized by intermittent hypoxic episodes through the night. The most frequently studied model of respiratory plasticity is respiratory long-term facilitation (LTF) following acute intermittent hypoxia (Mitchell *et al.* 2001, Feldman *et al.* 2003). Its conceptual development and possible mechanisms have been in the research focus for years, leading to conclusions regarding the modulation of the phrenic LTF (pLTF) (Bach and Mitchell 1996, Valic *et al.* 2010). However, a variety of factors such as periodicity versus continuity, intensity, duration and frequency of hypoxic episodes, and background oxygen level are shown to play an important role in the development of pLTF (Mateika and Sandhu 2011, Devinney *et al.* 2013, Dick *et al.* 2004, 2007, Bach and Mitchell 1998). Studies have revealed that brief episodes of simulated apnea (Mahamed and Mitchell 2008), and intermittent negative pressure applied to the upper airway (Ryan and Nolan 2009) can produce respiratory LTF. Furthermore, it has been shown that only periodic but not continuous hypoxic stimulus can

produce respiratory LTF (Baker and Mitchell 2000), showing that intermittency might be the most important factor for inducing LTF.

Whilst the consequences and benefits of intermittent hypoxic exposures have been extensively studied, the effects of repetitive hypercapnia have not been well documented despite the fact that it can also alter respiratory neural output. Contrasting results from previous studies reveal that episodic intracarotid hypercapnia induced pLTF (Morris *et al.* 1996), while systemic hypercapnia, which stimulated both central and peripheral chemoreceptors, caused respiratory long-term depression (LTD) (Bach and Mitchell 1998). Furthermore, it has been shown that severe intermittent hypercapnia (10 % CO₂) evoked LTD of the phrenic nerve activity (pLTD) in some experimental designs (Bach and Mitchell 1998), but failed to do so in similar studies (Baker *et al.* 2001) pointing to continuous stimulus as an adequate one to evoke pLTD (Kinkead *et al.* 2001). The reasons underlying this discrepancy are unknown but one possibility might be rat substrain differences. Furthermore, pattern dependence of LTD seen in previous studies might be partially explained by the activation of distinctive neurotransmitter systems. There is sufficient evidence to suggest that the respiratory control system is a complex neural circuit that integrates serotonergic and noradrenergic systems that interact in a "push-pull" manner in modulation of respiratory plasticity (Kinkead *et al.* 2001, Baker *et al.* 2001).

Respiratory plasticity following acute intermittent hypoxia is primarily expressed as a long lasting increase of phrenic nerve amplitude, whereas changes of the phrenic nerve burst frequency appear to be varying. While amplitude LTF might be the result of modulation of respiratory motor neurons (Fuller *et al.* 2000, Baker-Herman and Mitchell 2002, 2008), frequency LTF is most likely the result of brainstem respiratory rhythm generating neurons modulation (Baker-Herman and Mitchell 2008). On the other hand, opposing effects of episodic and continuous hypercapnia result in transient depression of the phrenic burst frequency (Bach and Mitchell 1998, Baker *et al.* 2001).

Previous studies of intermittent hypercapnia or hypoxia pointed to a puzzling feature of the respiratory control system (Harris *et al.* 2006, Mateika and Sandhu 2011, Devinney *et al.* 2013), indicating that altering the pattern of the stimulus might have an impact on the expression and magnitude of respiratory plasticity

(Mateika and Sandhu 2011). The majority of previous LTF studies have utilized acute intermittent isocapnic hypoxia as an inducing stimulus (Mitchell *et al.* 2001), but there is no published study demonstrating the effect of concomitant hypoxia and hypercapnia. Therefore, this study was undertaken to determine pattern sensitivity of phrenic nerve plasticity in respect to different respiratory challenges bringing them together into a single study on the same substrain of Sprague-Dawley rats, making the direct comparison more meaningful. We compared the long-term effects of intermittent and continuous hypercapnic and hypoxic stimuli on phrenic nerve plasticity. In addition, the novelty of this study was to investigate the impact of combined intermittent hypoxia and hypercapnia on phrenic nerve plasticity.

Material and Methods

The protocol for this study was approved by the Ethical Committee for Biomedical Research of the University of Split School of Medicine, Split, Croatia. All experiments were done in accordance with National Research Council's guide for the care and use of laboratory animals.

Experimental preparation

Experiments were conducted on 46 adult male Sprague-Dawley (Harlan, Italy) rats weighing 280-330 g (Animal facility of the University of Split School of Medicine). Anesthesia of a 20 % solution of urethane in 0.9 % saline (1.2 g/kg; supplemental dose 0.2 g/kg) was injected intraperitoneally. The adequacy of anesthesia was assessed by the absence of withdrawal reflex after noxious paw pinch.

The femoral artery and vein were cannulated bilaterally for blood pressure monitoring, blood sampling and drug injection. Blood samples for the determination of blood gases and pH (RapidLab 348, Bayer Diagnostics, Sudbury, UK) were taken at the regular intervals and arterial blood gases and pH were maintained within physiological limits by the adjustment of ventilation or infusion of bicarbonates, if needed. All animals were vagotomized bilaterally to eliminate pulmonary stretch receptors input. Rectal temperature was monitored by digital thermometer and maintained between 37 and 38.5 °C.

The trachea was cannulated through a midline ventral neck incision. The animals were artificially

ventilated through a tracheostomy using a respirator for small animals (SAR 830-P, CWE, Ardmore, USA). The initial parameters of artificial ventilation were a respiratory rate of 50 breaths/min, an inspiratory pressure of 12 cm H₂O, an inspiratory flow range 250–350 ml/min, and a positive end-expiratory pressure of 2–3 cm H₂O, and later they were adapted according to blood gases and capnography. The concentration of CO₂ was continuously monitored with a Gemini respiratory gas analyzer (CWE inc., Ardmore, USA) and adjusted by changing the respiratory rate and/or inspiratory time. The animals were paralyzed with the neuromuscular blocking agent rocuronium bromide (Organon, 50 mg in 5 ml, 1.33 mg/kg).

The rats were placed in a prone position in a stereotaxic instrument (Lab Standard, Stoelting, USA). The right phrenic nerve was dissected using the dorsal approach at the level of the C5 nerve rootlet, mounted on bipolar silver wire electrodes and covered with silicone gel to prevent from drying.

Experimental groups

Following surgical preparation, there were six experimental groups. Three groups were exposed to hypercapnia (15 % CO₂ in air), two to hypoxia (9 % O₂ in N₂), and one to combined hypercapnia and hypoxia (15 % CO₂ and 9 % O₂ in N₂).

Hypercapnic groups

Two groups of animals were exposed to five 3-min long episodes of intermittent hypercapnia, separated by 3-min recovery periods when the animals were ventilated either with room air (group AIHc, n=8), or with 50 % oxygen in N₂ (group AIHc_{O2}, n=6) to compare the impact of background oxygen level on hypercapnic responses. One group of animals was exposed to continuous hypercapnia for a duration of 30 min (group CHc, n=6). Prior to and following hypercapnic stimulation, CHc group was ventilated with room air.

Hypoxic groups

One group was exposed to five 3-min long episodes of acute intermittent hypoxia, separated by 3-min recovery periods when the animals were ventilated with a 50/50 oxygen/nitrogen mixture (group AIH, n=7). One group was exposed to 30 min of continuous hypoxia (group CH, n=7). Prior to and following hypoxic

stimulation, both groups, AIH and CH were ventilated with a 50/50 oxygen/nitrogen mixture.

Combined hypercapnia and hypoxia group

One group of animals (group AIHcH, n=8) was exposed to combined intermittent hypercapnia and hypoxia in the same manner (5 exposures each lasting 3 min, separated by a 3-min recovery period). Prior to and following stimulation, this group was ventilated with a 50/50 oxygen/nitrogen mixture.

To examine the effects of the anesthetic urethane and/or other time dependent factors on the viability and stability of preparation, experiments were conducted on an additional 5 rats (time-control) with the exception that these animals were not exposed to hypercapnia or hypoxia. Throughout the duration of the experiment there were no significant changes in the phrenic nerve activity, indicating the stability of the preparation (Carev *et al.* 2010, Pavlinac Dodig *et al.* 2012, Ivancev *et al.* 2013, Marinov *et al.* 2013).

Protocols

Following the completion of surgical procedures, a minimum of 30 min was allowed for the stabilization of phrenic nerve activity in baseline conditions. Baseline phrenic nerve activity was achieved by manipulating ventilator parameters while monitoring ET_{CO2} levels. The apneic threshold was determined and the initial PET_{CO2} was set about 3–4 mm Hg above this level. The control blood sample was taken prior to hypercapnic or hypoxic stimulus. During hypercapnia or hypoxia protocol blood sampling was avoided in order to minimize the overall blood volume loss from the animals. Arterial blood samples were taken at three post-hypercapnic or post-hypoxic periods (15, 30 and 60 min following the hypercapnic or hypoxic stimulus).

At the end of all the experiments, rats were euthanized with an overdose of urethane followed by an intravenous injection of potassium chloride.

Data acquisition and analysis

Phrenic nerve activity was amplified, filtered (band-pass 300 Hz - 10 kHz) and rectified. The moving-time average of phrenic nerve activity was obtained using the MA-1000 Moving Averager, System 1000 Modulator instrumentation (CWE Inc., Ardmore, USA) with a 50 ms time constant. The processed signal- phrenic neurogram (PNG) was recorded using the PowerLab system

(ADInstruments, Castle Hill, Australia) and analyzed by PowerLab software, Chart for Windows version 5.4.2 and Scope for Windows version 3.8 (ADI Instruments, Castle Hill, Australia). There were nine time points for data analysis: before the first hypercapnia/hypoxia (T0), during hypercapnic/hypoxic episodes 1-5 (TH1-TH5), and 15 (T15), 30 (T30) and 60 (T60) min after the last hypercapnic/hypoxic stimulation. From the digital record of the phrenic nerve activity, we analyzed peak phrenic nerve activity (pPNA), phrenic burst frequency (f), inspiratory duration (T_i), expiratory duration (T_e) and respiratory cycle total duration (T_{tot}). The phrenic nerve activity was averaged once it had reached the steady-state, and a minimum of a 20 s signal was required for successful analysis. Average amplitude data were normalized as the percentage change from baseline activity (immediately before the first hypercapnia or hypoxia).

Data were analyzed using MedCalc (Ostend, Belgium). A one- and two-way repeated measures ANOVA (within and between groups) was performed followed by Bonferroni *post-hoc* correction to provide information for all pair wise comparisons of interest within groups at the same time point during the protocol. Data were presented as mean \pm SEM. A P-value of 0.05 was considered statistically significant.

Results

Effects of hypercapnic stimuli

Acute intermittent hypercapnia evoked depression of the respiratory frequency 60 min after the end of the last hypercapnic stimulus, i.e. respiratory frequency decreased from 44.25 ± 4.06 breaths/min at T0 to 35.29 ± 5.21 breaths/min at T60 in the AIHc group ($P=0.038$; Figs 1 and 2), and from 45.5 ± 2.62 breaths/min at T0 to 37.17 ± 3.68 breaths/min at T60 in the AIHc_{O₂} group ($P=0.049$), showing that frequency pLTD was developed. However, exposure to acute intermittent hypercapnia protocol did not evoke persistent long-lasting changes of the pPNA 60 min after the end of the stimuli ($-4.8 \pm 21.6\%$ in the AIHc group, $P=1$; Figs 1 and 3, and $-22.3 \pm 11.6\%$ in the AIHc_{O₂} group, $P=0.67$).

Continuous hypercapnia failed to evoke frequency pLTD 60 min after the end of the stimulus, i.e. respiratory frequency was 40.29 ± 2.69 breaths/min at T0, and 38.14 ± 2.04 breaths/min at T60 in the CHc group ($P=1$). Continuous hypercapnia did not evoke

significant long-lasting changes of the pPNA 60 min after the end of the stimulus compared to baseline ($+39.3 \pm 30.2\%$ in the CHc group, $P=1$).

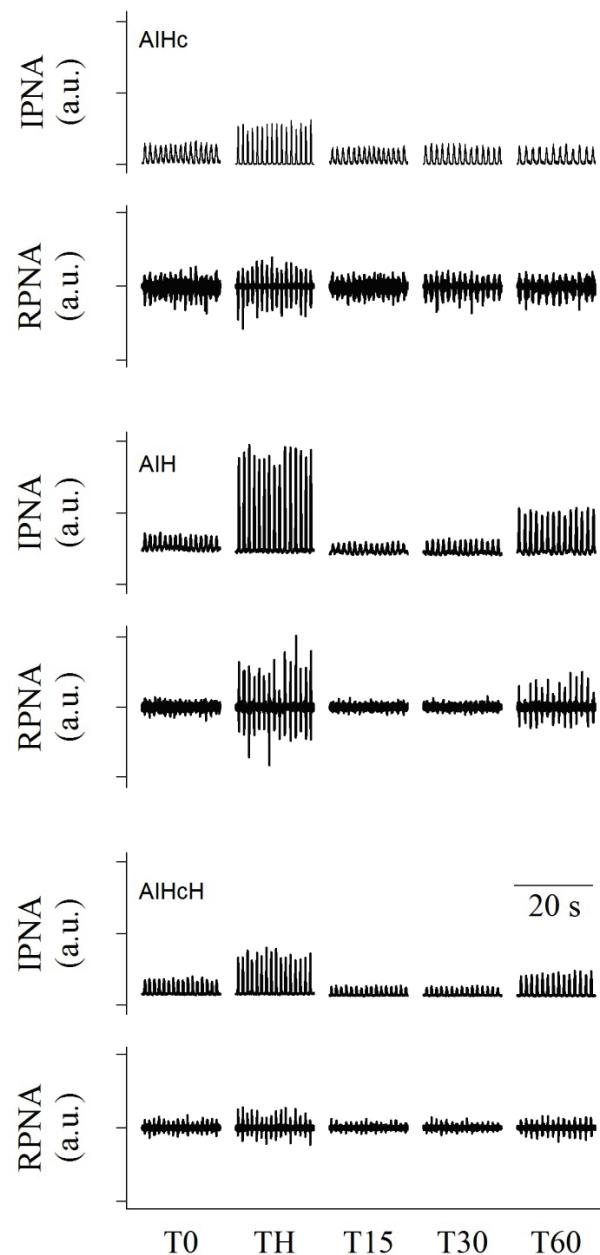

Fig. 1. Responses of integrated phrenic nerve activity (IPNA; arbitrary units, a.u.) and raw phrenic nerve activity (RPNA; arbitrary units, a.u.) following hypercapnic (AIHc), hypoxic (AIH), and combined hypercapnic and hypoxic stimuli (AIHcH) in three rats. AIHc rat was exposed to acute intermittent hypercapnia, showing depression of the respiratory frequency at T60 (frequency pLTD). AIH rat was exposed to acute intermittent hypoxia, indicating pLTF at T60. Combined hypercapnia and hypoxia elicited non-significant increase in pPNA at T60. The phrenic nerve activity is shown during baseline conditions (T0), at the hypercapnic or hypoxic episode (TH), and 15 (T15), 30 (T30), and 60 (T60) min after the end of the last hypercapnic or hypoxic stimulus.

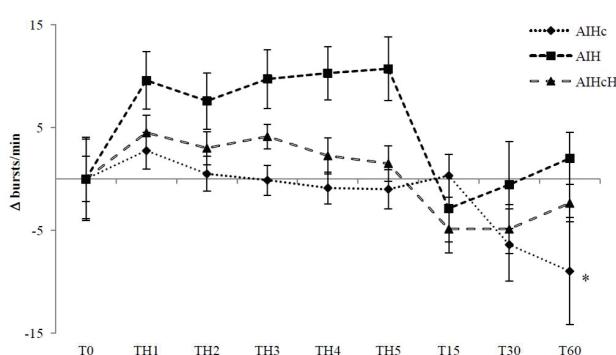

Fig. 2. Time course of changes in the phrenic burst frequency (Δ bursts/min) in groups exposed to hypercapnic (AIHc), hypoxic stimulation (AIH), and combined hypercapnic and hypoxic stimulation (AIHcH). Acute intermittent hypercapnia evoked frequency phrenic long-term depression (pLTD) 60 min after the end of the last hypercapnic stimulus. * Significantly different from baseline values, $P<0.05$. T0 refers to baseline value before hypercapnia or hypoxia; TH1-5 represent five hypercapnic episodes, whereas T15, T30, and T60 are time points at 15, 30, and 60 min after the end of the hypercapnic or hypoxic stimulus.

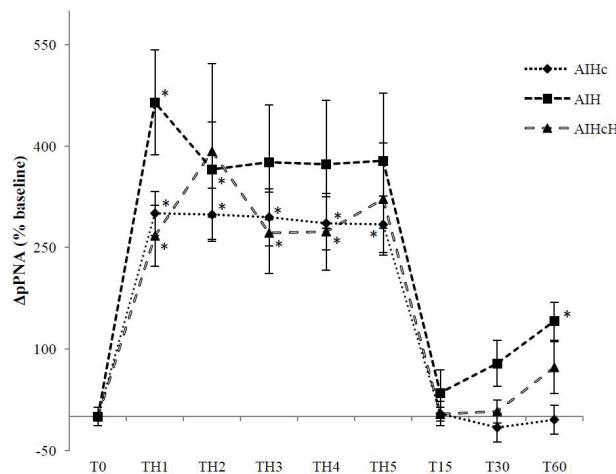

Fig. 3. Time course of changes in the peak phrenic nerve activity (pPNA) in groups exposed to hypercapnic stimulation (AIHc), hypoxic stimulation (AIH), and combined hypercapnic and hypoxic stimulation (AIHcH). Exposure to AIH protocol evoked phrenic long-term facilitation (pLTF) at T60. * Significantly different from baseline values, $P<0.05$. T0 refers to baseline value before hypercapnia or hypoxia; TH1-5 represent five hypercapnic or hypoxic episodes, whereas T15, T30, and T60 are time points at 15, 30, and 60 min after the end of the hypercapnic or hypoxic stimulus.

Effects of hypoxic stimuli

Acute intermittent hypoxia did not evoke significant long-lasting changes of the respiratory frequency 60 min after the end of the stimuli, i.e. frequency was 37.71 ± 3.87 breaths/min at T0 and

39.71 ± 2.55 breaths/min at T60 ($P=1$; Figs 1 and 2). Still, acute intermittent hypoxia elicited a significant increase of pPNA at T60, i.e. pPNA increased by 141.0 ± 28.2 % compared to baseline ($P=0.015$; Figs 1 and 3), showing that pLTF developed.

Continuous hypoxia failed to evoke significant long-lasting changes of both, respiratory frequency (43.71 ± 2.36 breaths/min at T0 and 38.86 ± 2.73 breaths/min at T60, $P=1$), and pPNA ($+22.8\pm47.4$ %, $P=1$) 60 min after the end of the stimulus.

Effects of combined hypoxic and hypercapnic stimuli

Combined acute hypercapnia and hypoxia failed to evoke significant long-lasting changes of respiratory frequency 60 min after the end of the last stimuli. Respiratory frequency in AIHcH group was 40.5 ± 2.2 breaths/min at T0 and 38.14 ± 1.82 breaths/min at T60 ($P=1$; Figs 1 and 2). Combined hypoxic and hypercapnic stimulation failed to evoke significant change of the pPNA 60 min after the last stimulus compared to baseline values ($+72.6\pm38.4$ %, $P=1$; Figs 1 and 3).

Regarding respiratory cycle parameters, there were no significant changes in T_i , T_e , and T_{tot} at 15, 30, and 60 min after hypercapnic or hypoxic stimuli compared to baseline values in any group of the animals, as shown in Table 1. A significant change in respiratory rate should have also resulted in a significant change in T_{tot} and a lack thereof suggests that, because of the variability of the data, the study was underpowered to detect changes in respiratory timing.

Exposure to either intermittent (TH1-5) or continuous hypercapnic or hypoxic stimuli elicited an increase of pPNA in all groups of animals (Figs 1 and 3), but failed to significantly change respiratory frequency during the exposures (Figs 1 and 2).

There were no significant changes in PaO_2 , $PaCO_2$, and pH values at T0, T15, T30, and T60 in any experimental group, as shown in Table 2.

Mean arterial pressure (MAP) tended to increase during the hypercapnic and combined hypercapnic/hypoxic exposures and decreased during hypoxic exposures and then returned to baseline levels. Following exposures, MAP was successfully maintained relative to baseline in all experimental groups of animals until the end of the experiments.

Data are presented as mean \pm SEM. T0, baseline value before hypercapnia or hypoxia; T15, T30, and T60, 15, 30, and 60 min after the stimulus.

Discussion

The results of this study showed that acute intermittent hypercapnia evoked the development of frequency pLTD in anesthetized rats. In animals exposed to the acute intermittent hypoxia protocol, amplitude pLTF was elicited 60 min after the end of the last hypoxic stimulus, i.e. pLTF was induced. Combined intermittent hypercapnia and hypoxia as well as continuous hypercapnia or hypoxia failed to induce phrenic nerve plasticity 60 min after the end of the last hypercapnic/hypoxic stimulus. Thus, it appears that intermittency of the hypercapnic or hypoxic stimulus is needed to evoke distinct forms of respiratory plasticity.

The majority of previous studies investigating mechanisms of hypercapnia induced respiratory plasticity used the model of urethane anesthetized rats exposed to three 5-min long hypercapnic stimulations separated by normocapnic recovery periods (Bach and Mitchell 1998, Baker *et al.* 2001). Although repeated intracarotid injections of CO_2 saturated saline evoked pLTF, systemic exposure to intermittent hypercapnia resulted in pLTD (Morris *et al.* 1996, Bach and Mitchell 1998). Similarly, in our study, systemic exposure to the protocol of acute

intermittent hypercapnia resulted in long lasting depression of the phrenic nerve frequency and had no long lasting effects on phrenic nerve amplitude. Systemic application of high levels of CO_2 stimulates both central and peripheral chemoreceptors resulting in the facilitation of the phrenic nerve during exposure. Morris and colleagues (1996) injected CO_2 saturated saline directly into the carotid artery and stimulated mainly carotid chemoreceptors, with minimal effects on the central nervous system (Morris *et al.* 1996). Thus, one might presume that the central effects of high levels of CO_2 are crucial in the development of ventilatory depression. Moreover, it was suggested that hypercapnia induces an increase of extracellular HCO_3^- , and as increased concentrations of HCO_3^- in the brain persist long after cessation of hypercapnia, it could be associated with long lasting depression of the phrenic nerve (Bach and Mitchell 1998). Still, in our study blood pH levels were maintained throughout the protocol and frequency pLTD developed late (60 min) after cessation of hypercapnic stimulation, so we do not assume that the elevated levels of brain HCO_3^- could be responsible for the observed frequency pLTD. In addition, in our study continuous hypercapnia failed to evoke frequency pLTD.

On the other hand, in our study both intermittent and continuous hypercapnia protocols failed to evoke amplitude pLTD. Cumulative effects of severe, continuous hypercapnia on the noradrenergic system were suggested to be the reason for the development of pLTD in some studies (Baker *et al.* 2001). However, continuous hypercapnia in our study failed to evoke pLTD. A possible explanation might be that the pattern sensitive signaling processes indicating that intermittent, but not continuous stimulus enhances gene expression important in long-lasting neuronal plasticity and long-term memory formation (Freudenthal and Romano 2000). In our study, the lack of apparent amplitude pLTD following intermittent hypercapnia might be the consequence of the simultaneous development of serotonin dependant pLTF, which counterbalanced the noradrenalin dependant pLTD.

In the last two decades, pLTF evoked by acute intermittent hypoxia was in the research focus of many studies (Fuller *et al.* 2000, Dale-Nagle *et al.* 2010, Mitchell *et al.* 2001). It is known that pLTF depends on the serotonergic neuromodulation, as well as the specific pattern and timing of stimulus performance (Pavlinac *et al.* 2011, Pecotic *et al.* 2009, Valic *et al.* 2010, Mateika and Sandhu 2011). Results from our study confirm previous research regarding the importance of periodicity of hypoxic stimulation in the development of respiratory plasticity, since only acute intermittent, but not continuous hypoxia evoked pLTF.

Our results are in accordance with previous studies investigating LTF in anesthetized rats (Bach and Mitchell 1996, Pavlinac *et al.* 2011) which reported a decrease in blood pressure during hypoxic exposures. Although hypoxia results in strong sympathetic stimulation mediated by chemosensitive cells in carotid bodies (Zoccal *et al.* 2014), it seems that the hemodynamic response may depend on the level of hypoxia (Sabino *et al.* 2013). Indeed, hypoxia with 8, 10, or 15 % O₂ produced slight hypotension independent of carotid chemoreceptors that might be explained by the release of adenosine acting on endothelial A₁ receptors to stimulate the synthesis and release of NO which induces vasodilatation and consequent hypotension (Ray and Marshall 2005).

We are aware that the mixture of 15 % CO₂ in air would refer to decreased PaO₂ in our protocol possibly leading to mild-hypoxic-hypercapnic exposure. However, gas mixture of 15 % CO₂ in air would lead to the reduction of O₂ in that mixture to about 17-18 % which

would represent only mild hypoxic stimulus that could not evoke long term changes of the phrenic nerve activity (Mateika and Sandhu 2011) and thus should not interfere with the final result. In addition, in order to investigate severe hypoxic (9 % O₂) and severe hypercapnic stimulus (15 % CO₂) we performed a separate set of experiments using combination of 9 % O₂ and 15 % CO₂ in nitrogen. Although hyperoxic hypercapnia used in the literature (Bach and Mitchell 1998) represents better choice to avoid confounding effect of hypoxic stimulus, we believe that hypoxic stimulus using 15 % CO₂ in air was not sufficient to affect phrenic LTF or LTD.

The biological and clinical significance of intermittent hypoxia has been well recognized in recent years. It has been suggested that intermittent hypoxia might have a beneficial role in sleep related breathing disorders and could be a viable means of restoring respiratory functions in ventilatory control disorders (Mateika and Narwani 2009, Gaultier 2008). However, although intermittent hypercapnia results in altered respiratory control, its short and long-term effects on respiratory control remain poorly studied (Steggerda *et al.* 2010).

In this study, we did not determine neurotransmitters involved in respiratory plasticity, exact mechanisms, and the precise site of action in the development of pLTD and pLTF. However, different protocols gave us insights into the importance of stimulus periodicity in the induction of distinct forms of respiratory plasticity. Some of the previous studies were conducted in background hyperoxia (50 % O₂) to avoid additional hypoxic stimulus between challenging episodes (Bach and Mitchell 1998). However, high background levels of O₂ might affect expression of pLTF and pLTD. In our study, some protocols were conducted in background normoxia (air, 21 % O₂) because high levels of inspired O₂ inhibit the action of CO₂ and the peripheral chemoreceptors (Fitzgerald and Parks 1971).

Bearing in mind that intermittent hypoxia might have an important beneficial role in many pathological conditions (Dale *et al.* 2014), one might speculate about the physiological significance of hypercapnia induced respiratory plasticity. In our study hypercapnic exposures were severe (15 %) which is not likely to be seen in clinical practice, even in severe lung diseases or sleep disordered breathing. We are aware of the fact that at this level CO₂ might have actions that are not related only to chemoreception. However, we believe that mechanistic insights into hypercapnia and combined hypercapnia and

hypoxia induced respiratory plasticity might be useful in understanding respiratory plasticity and its role in different pathological conditions.

Previous studies showed that pLTD could be evoked following intermittent hypercapnic stimulus. The possible mechanisms of pLTD were proposed, indicating that hypercapnia-induced release of norepinephrine could act on α_2 -adrenergic receptors located on raphe serotonergic neurons to inhibit raphe excitability and release of serotonin. In our study, pLTD could be evoked if acute intermittent hypercapnic stimulus was performed, but not if concomitant hypercapnic and hypoxic stimuli were applied. Our results, in accordance with numerous previous studies confirmed that acute intermittent hypoxia induces the development of pLTF. However, in our study if acute intermittent hypoxia was combined with acute intermittent hypercapnia, pLTF was attenuated. It is well known that carbon dioxide levels might alter LTF expression in animals (Bach and Mitchell 1996, Fregosi and Mitchell 1994, Harris *et al.* 2006). It is possible that hypercapnia-induced activation of noradrenergic neurons in our study inhibited raphe serotonergic neurons and consequently led to attenuation of pLTF.

The impact of intermittent versus sustained hypercapnia and/or hypoxia on phrenic nerve plasticity

was investigated and reported in numerous studies often using different species, substrains and protocols. In this study we present evidence about the pattern sensitivity of phrenic nerve plasticity in respect to different respiratory challenges compared in a single study on the same substrain of Sprague-Dawley rats. The results of this study indicate that acute intermittent hypercapnia elicits frequency pLTD, whereas acute intermittent hypoxia elicits amplitude pLTF in anesthetized rats. Combined hypercapnia and hypoxia, as well as continuous hypercapnic or hypoxic stimulus failed to evoke phrenic nerve plasticity. Thus, we conclude that intermittency of the hypercapnic or hypoxic stimulus is needed to evoke distinct forms of phrenic nerve plasticity.

Conflict of Interest

There is no conflict of interest.
